Human adults can combine perceptual estimates from different senses to minimize uncertainty, by taking a reliability-weighted average (the maximum likelihood estimate, MLE). Although research has shown that healthy human adults reweight estimates as their reliability changes from one trial to the next, less is known about how humans adapt to gradual long-term changes in sensory reliability. This study assessed whether individuals diagnosed with progressive visual deterioration, due to retinal disease, combined auditory and visual cues to location according to optimal (MLE) predictions. Twelve patients with central visual loss, 10 patients with peripheral visual loss, and 12 normally sighted adults were asked to localize visual and/or auditory targets in central (1°–18°) and peripheral (36°–53°) locations. Normally sighted adults and patients with peripheral visual loss showed multisensory uncertainty reduction and cue weighting in line with MLE predictions. In contrast, patients with central visual loss did not weight estimates appropriately in either the center or the periphery, and failed to meet MLE predictions in the periphery. Our results show that one visual loss patient group succeeded at optimal cue combination, whereas the other patient group (patients with central vision loss) did not. We propose that sensory remapping due to changes in fixation behavior may contribute to apparent failures in the latter group.

Public Significance Statement
We examined how patients with gradual vision loss combined their deteriorating visual sense with audition (hearing) to localize targets. Humans usually combine different senses optimally, by taking their differing reliabilities into account, but it was not known whether patients with sensory loss would also succeed in this. Patients with gradual central vision loss did not combine visual and auditory estimates of location according to their reliabilities, whereas patients with gradual peripheral vision loss—and normally sighted adults—did. These results indicate that humans do not always combine sensory estimates optimally following gradual sensory changes. Some patients may have performed suboptimally because they may have learnt to fixate eccentrically, which could have changed the mapping between locations of visual and auditory targets. The results highlight the need to also consider possible changes to cross-sensory mappings in children and older adults, who have also been found to combine sensory estimates suboptimally.

Keywords: multisensory combination, audio-visual localization, progressive visual loss, reliability-weighted averaging
In daily life we continuously receive complementary information about our environment from multiple senses. These sensory signals often provide “redundant” information about the same physical property/event. For example, when deciding whether it is safe to cross the road, we can look and listen for approaching traffic and thereby make a judgment based on both visual and auditory estimates. Humans can use sensory redundancy to minimize perceptual uncertainty, by taking a reliability-weighted average of each uni-sensory estimate, known as the maximum likelihood estimate (MLE; Ernst, 2006).

A large body of research has found that human adults combine sensory estimates according to this optimal MLE model, (e.g., Alais & Burr, 2004; Ernst & Banks, 2002; Gepshtein & Banks, 2003; Helbig & Ernst, 2007). For example, Alais and Burr (2004) asked human adults to localize briefly presented visual Gaussian blobs and/or auditory clicks presented in central space (±20°). Results showed that human adults minimized the uncertainty of their bimodal location estimates, indicating that they were combining visual and auditory location estimates optimally. Moreover, as the reliability of the visual cue decreased (when the stimulus was made more blurred), participants increased the weight that they assigned to the auditory information, demonstrating that they were weighting cues according to their relative reliability.

Researchers have shown that adults are able to reweight signals if their relative reliability changes from one trial to the next (e.g., Alais & Burr, 2004; Ernst & Banks, 2002). However, less is known about how human adults adapt to the gradual changes in sensory reliability that occur during aging or disease. Children and older adults have been found to weight cues suboptimally in multisensory tasks (Bates & Wolbers, 2014; Gori, Del Viva, Sandini, & Burr, 2008; Nardini, Begus, & Mareschal, 2013). For example, in a navigation task, Bates and Wolbers (2014) found that older adults weighted vision less (and nonvisual, e.g., vestibular information, more) than predicted by the relative reliabilities of the cues, whereas, consistent with earlier research (Nardini, Jones, Bedford, & Bradlick, 2008), younger adults showed optimal cue combination. In development and aging the reliabilities of different senses are gradually changing. For example, vestibular anatomical changes that occur during aging can gradually affect the reliability of vestibular information for completing certain behavioral tasks (Anson & Jeka, 2016). Consequently, children and older adults may weight sensory information suboptimally because they have not fully accounted for gradual changes to the reliability of their senses. Given that adults are able to reweight sensory cues from trial to trial, in line with short-term experimental manipulations to the cue reliabilities, (e.g., Alais & Burr, 2004; Ernst & Banks, 2002), why might they fail to account for longer-term changes?

How the nervous system accounts for uncertainty is not yet clear (Ma, Beck, Latham, & Pouget, 2006; Ohshiro, Angelaki, & DeAngelis, 2011), but an interesting possibility raised by the results of studies in children and older adults (Bates & Wolbers, 2014; Gori et al., 2008; Nardini et al., 2013) is that longer-term changes in sensory reliability are dealt with differently from short-term trial-to-trial changes. For example, there could be a general reliability setting for a particular sensory cue (e.g., a visual cue to location; Alais & Burr, 2004) that is immediately modulated by the specific sensory information on a particular trial, but whose overall setting is more difficult to change. However, in development and aging there is also the possibility that the cue combination process itself is immature or deficient (e.g., Dekker et al., 2015), and consequently age-related changes in reliability do not offer a clear way to address this question. Here we instead ask how patients who are experiencing gradual loss of a sense (vision) account for this during audio-visual cue combination. Surprisingly, despite considerable recent interest in Bayesian models of cue combination (e.g., Trommershäuser, Kording, & Landy, 2011), we know of no other studies to date that have compared cue combination by patients experiencing gradual visual loss with Bayesian predictions.

Retinal degenerative diseases, including retinitis pigmentosa and macular degeneration, lead to progressive visual deterioration that is often, at least initially, limited to certain parts of the visual field. Consequently, in such cases, the nervous system must account for both deteriorations in visual reliability and changes in visual reliability across the visual field. Even in normally sighted adults, the reliability of vision changes across the visual field, with visual precision decreasing as a function of eccentricity due to changes in the density of photoreceptors (Dacey & Petersen, 1992). Previous research has not assessed whether normally sighted human adults weight vision optimally in peripheral (>20 degrees) as well as central space. However, Charbonneau, Veronnne, Boudrias-Fournier, Lepore, and Collignon (2013) found that the visual capture of spatially misaligned auditory information in human adults declines with eccentricity, suggesting that adults do reduce their reliance on vision in audio-visual peripheral spatial decisions.

Interestingly, auditory localization thresholds also deteriorate with eccentricity, and so individuals with normal sight and hearing show increased localization uncertainty for auditory (Mills, 1958; Perrott, 1984) and visual stimuli (Perrott, Costantino, & Cisneros, 1993) in peripheral compared to central locations. Consequently, although the relative reliability of visual and auditory cues may change across the visual field (depending on the stimuli to be localized), increased eccentricity generally has a deleterious effect on the reliability of both cues. In individuals with progressive visual loss, the additional central and/or peripheral loss would be expected to change the relative reliabilities of the two senses markedly in comparison to controls. However, changes in the relative reliability of visual and auditory cues may be further complicated by compensatory changes in residual sensors. For example, (early and late-onset) blind humans and animals show enhanced auditory target detection (Fieger, Roder, Teder-Salejarvi, Hillyard, & Neville, 2006) and auditory localization (King & Parsons, 1999; Rauschecker & Kniepert, 1994; Voss et al., 2004) on certain tasks. Although the effect of partial vision loss on residual senses is less clear, some findings suggest blind individuals with residual vision show changes in nonvisual processing too (Cunningham, Weiland, Bao, & Tjan, 2011; Lessard, Pare, Lepore, & Lasonde, 1998).

Here we assessed whether human adults experiencing progressive visual deterioration weight and combine visual and auditory cues to location optimally, that is, in line with MLE predictions. Normally sighted adults and those diagnosed with a retinal degenerative disease causing primarily either central or peripheral visual loss were asked to localize stimuli using vision alone, hearing alone, or both together. Measured visual weights and measured bimodal estimates were compared to MLE predictions. This allowed us to ask, Do patients who are losing vision account for any deterioration in visual reliability (i) optimally, in much the same
way that normally sighted adults account for experimental manipulations of visual reliability, or (ii) suboptimally, as has been observed in younger and older adults experiencing gradual changes to their senses.

Methods

Ethics Statement

Patients were recruited from Moorfields Eye Hospital NHS Foundation Trust, London, UK, and normally sighted adults were recruited through the UCL psychology online subject pool. The study received approval from the London Hampstead research ethics committee. Informed written consent, according to the Tenets of the Declaration of Helsinki, was obtained from all participants prior to participation.

Participants

Participants were 12 adults with central vision loss (7 male, M = 49.2 years, SD = 11.5 years), 10 adults with peripheral vision loss (7 male, M = 40.9 years, SD = 10.4 years; see Table 1), and 12 age-matched normally sighted adults (6 male, M = 48.5 years, SD = 16.0 years). Participants were identified as having either primarily central or peripheral vision loss by their clinician (MM), on the basis of their diagnosis, clinical findings, and results of investigations (retinal imaging and visual field testing), upon attending an appointment at Moorfields Eye Hospital. Most participants with central vision loss (10/12) had been diagnosed with Stargardt Disease (Rotensteinreich, Fishman, & Anderson, 2003), whereas most participants with peripheral vision loss (9/10) had been diagnosed with Retinitis Pigmentosa (Hartong, Berson, & Dryja, 2006). Note that participants diagnosed with peripheral vision loss had progressive retinal conditions that affect peripheral vision in the first instance with central visual loss later in the disease process. However, at the time of this study, their peripheral vision was most severely affected, and their central visual fields (up to 18 degrees) were relatively preserved. Five participants with peripheral vision loss (IDs 06, 07, 08, 09, 10) were not able to complete the auditory-visual localization task in peripheral space (described below), because they were unable to detect the visual targets presented in the periphery. Participants identified as having central vision loss had retinal conditions that affected the cells in their macular (central) vision only (isolated macular dystrophy). All normally sighted adults had visual acuities of between −0.18 and 0.16 logMAR (Snellen equivalent of between 6/4 and 6/9), as assessed using a logMAR letter chart. A logMAR score of 0 (Snellen equivalent of 6/6) indicates that the observer can resolve details as small as 1 min of visual angle. A logMAR score of 0.3 (Snellen equivalent of 6/12) indicates that the observer can resolve details as small as 2 min of visual angle. All participants reported having normal hearing.

Note. Snellen visual acuity is reported. In the Snellen fraction, the numerator represents the distance at which the participant would need to approach to read letters that an observer with normal acuity could read from the distance reported in the denominator. Hence, a participant with 6/12 acuity would need to approach a distance of 6 m to read letters that an observer with normal acuity could read at 12 m.

* Participants with peripheral vision loss who were not able to complete the auditory-visual localization task in peripheral space.

Apparatus and Stimuli

Stimuli were presented using 122 light-emitting diode pixels (Adafruit 12 mm diffused flat digital RGB LED pixels; see Jones, Garcia, & Nardini, 2015) and 9 speakers (50 mm × 90 mm Visaton speaker SC 5.9), mounted on a 2.5 m semicircular ring (circle radius: 2.87 m), spanning −15 to +30 degrees (see Figure 1). A further 2 light-emitting diode pixels (LEDs) and 1 speaker were mounted on the wall, 20 degrees left of the ring, and served as the fixation target during peripheral stimuli presentation. Stimulus presentation was controlled using Matlab (Version R2014a, The MathWorks Inc., Natick, Massachusetts, United States) and the Psychophysics toolbox extensions (Brainard, 1997; Kleiner, Brainard, & Pelli, 2007; Pelli, 1997), on a Windows 7 computer. An Arduino Uno microcontroller (SmartProjects, Strambino, Italy) was used to interface between the control computer and the LED pixels. The Matlab PsychPortAudio ASIO interface controlled audio presentation via a Focusrite Saffire PRO 40 sound card, and audio signals were amplified using Lypin Hi-Fi 2.1 stereo amps. The sampling rate was 44.1 kHz and speakers were equalized for intensity using a sound level meter.

All 122 LEDs were powered to show white light (2223 cd/m²) constantly throughout the duration of the experiment. The visual stimulus was a 25 msec flash of white light from 50 adjacent LEDs, (spaced 0.5° apart, spanning 25°). The luminance of the visual stimulus was increased for peripheral (3055 cd/m²) compared to central (2639 cd/m²) space, to account for the approximate doubling of Differential Luminance Sensitivity (DLS) from 36° to 1° (Brenton & Phelps, 1986). The luminance of the visual stimulus was also increased for participants with vision loss, where necessary, to increase the reliability of the visual stimulus. This was assessed using a short practice task of 32 trials (described below). Where a participant was unable to discriminate between the standard and the comparison...
stimuli at the largest discrimination distances (13° & 18°), the luminance of the visual stimulus was increased, and the practice task was repeated. Audio stimuli were 100 msec (25 ms rise and 25 ms fall time) band-pass-filtered noise bursts (tenth octave centered on 1000 Hz) presented at 50 dB SPL (± 1 dB), presented against a continuously played background pink noise presented at 20 dB SPL. Note that in an attempt to more closely match visual and auditory cue reliability for location, the visual stimulus duration (25 ms) was shorter than the auditory stimulus duration (100 ms).

Procedure

Participants were asked to localize visual (light flash) and auditory (noise burst) stimuli presented separately or together, in a dimly lit, quiet room. Each trial began with the presentation of a fixation cue at 0 degrees (i.e., straight ahead), consisting of a red 400 msec light flash from two LEDs (13 600 cd/m²) and a simultaneous 400 msec 500 Hz (50 dB SPL) tone played from the corresponding speaker. Participants were asked to maintain their eye gaze in this direction throughout the whole experiment, and a chin-rest (with forehead-rest) was used to fix their head position. They were instructed to maintain both eyes open throughout the experiment (including during the audio-only trials), and to maintain their head as still as possible. All participants appeared to comply. Following the fixation cue, two sets of stimuli were presented successively: a standard (central: 1°, peripheral: 36°, right of fixation) and one of eight comparison stimuli (0°–17° right of the standard). The order of the standard and comparison presentation was counterbalanced. The commencement of the second stimulus succeeded that of the first by 500 ms. Participants were asked to press a key to indicate whether the first or second stimulus was further to the right. A stimulus consisted of a flash of light, a noise burst, or both together, and the type of stimulus varied between blocks. For example, during a visual-localization block, participants were asked, “Was the first flash or the second flash further to your right? Press ‘1’ if first, ‘2’ if second.”

Blocks consisted of audio-only, vision-only, or bimodal (audio-visual) stimuli. Where visual and auditory stimuli were presented together, either stimuli were presented in congruent locations (no-conflict), or the visual stimulus was displaced leftward (central: by 3°, peripheral: by 4°) compared to the auditory stimulus (conflict). The conflict trials were used to measure cue weighting.

The experiment was divided into two parts, one part consisting of localization in central space (central condition), the other of localization in peripheral space (peripheral condition). The order of these was counterbalanced (by the experimenter) across participants. Note that the set-up in central and peripheral conditions was exactly the same, except that participants were rotated leftward by 35 degrees in the peripheral condition.

Prior to commencing the test blocks for central and peripheral tasks, participants completed two practice blocks, one with each of the unimodal stimuli used in the experiment. During testing, they completed 24 test blocks (6 audio-only, 6 vision-only, 12 audio-visual) of 64 trials, at each location (central and peripheral). Each block included 8 trials at each of the following comparison angles: 1°, 2°, 3°, 4°, 6°, 9°, 13°, and 18°. Equal numbers of conflict and no-conflict trials were randomly interleaved within audio-visual blocks. Thus, there were equal numbers of trials that were audio-only, visual-only, audio-visual (consistent), and audio-visual (conflict). There were 48 trials per comparison distance for each of these conditions (see Table 2).

On average, the experiment took 5 hours in total to complete. At the end of each experimental block, participants were required to press a button to commence the next block, or had the option to take a break if needed. Hence, participants were able to take breaks frequently, as and when needed. They were asked to take at least

Data Analysis

The proportion of trials in which the second stimulus was perceived as being to the right of the first was plotted against the size of the displacement between the two stimuli, for each cue (audio-only, vision-only, audio, and vision: no conflict and conflict), and for each location (central, peripheral). Data were fitted with cumulative Gaussian functions, using Psignifit toolbox version 2.5.6 for Matlab (see http://bootstrap-software.org/psignifit/), a software package that implements the maximum-likelihood method described by Wichmann and Hill (2001). The standard deviation (σ) and the mean (μ) of each function provided, respectively, estimates of the cue’s reliability and point of subjective equality (PSE). Hence, the standard deviation of each function provides a measure of the cue’s uncertainty (which is inversely proportional to the cue’s reliability). Functions were fitted to each individual participant’s data (see Figure 2).

The maximum likelihood estimate is given by the mean of the single cue estimates, $\hat{s}_{AV}$, weighted by their respective reliabilities:

$$\hat{s}_{AV} = w_v\hat{s}_v + w_a\hat{s}_a$$  

(1)

where $\hat{s}_v$ is the visual estimate, $\hat{s}_a$ is the auditory estimate, and $W_v$ and $W_a$ are the optimal relative weights for each modality, inversely proportional to their variances, ($\sigma^2$):

$$w_v = \frac{1/\sigma_v^2}{1/\sigma_v^2 + 1/\sigma_a^2} = \frac{\sigma_a^2}{\sigma_a^2 + \sigma_v^2}$$  

(2)

$$w_a = \frac{1/\sigma_a^2}{1/\sigma_v^2 + 1/\sigma_a^2} = \frac{\sigma_v^2}{\sigma_a^2 + \sigma_v^2}$$  

(3)

Thus the maximum likelihood estimate (MLE) produces a final estimate with the lowest possible variance (i.e., uncertainty):

$$\sigma_{AV} = \frac{\sigma_v^2\sigma_a^2}{\sigma_a^2 + \sigma_v^2}, \text{ where } \sigma_{AV} \leq \min(\sigma_a^2, \sigma_v^2)$$  

(4)

For each participant, measured unimodal reliabilities ($\sigma$) were used to compute the MLE prediction, and their measured bimodal reliability was compared to this prediction.

The PSE describes the point at which participants were equally likely to perceive the comparison stimulus as left or right of the standard. To assess whether participants weighted cues optimally during their localization estimates, no-conflict and conflict PSEs were used to compute the actual weighting given to vision in bimodal trials (Eq. 4), and this was compared with the predicted optimal visual weight (Eq. 2).

$$\hat{w}_V = \frac{PSE_{Conflict} - PSE_{No\ Conflict}}{\text{Visual\ Displacement}}$$  

(5)

Thus, a difference in conflict and no conflict PSEs equal to the size of the visual displacement would indicate that partici-

---

Figure 2. Data from a representative normally sighted participant (A) and a participant with central vision loss (B), in the Central Localization Task. For the normally sighted participant, localization with vision alone was more reliable than with audition alone, reflected by the steeper slope of the psychometric curve (and thus lower $\sigma$). Larger marker points indicate points of subjective equality (PSEs) for the Bimodal (no conflict) and Conflict conditions. In the Conflict condition, the comparison visual stimulus was displaced leftward by 3 degrees. This conflict shifted the participant’s psychometric function rightward by 2.6°. From this we conclude that this participant relied relatively more on vision than on audition during bimodal conditions, with an estimated vision weight of 0.87 ($w_v = 2.6/3 = 0.87$). Note that in the experiment, all comparison stimuli in no-conflict conditions were right of the standard stimulus. The negative numbers on the x-axis reflect trials in which the comparison stimulus was presented first. See the online article for the color version of this figure.
pants relied entirely on visual information in their bimodal localization judgments, whereas no difference in PSEs would indicate that participants relied entirely on auditory information (see Results, Figure 2, for an example participant’s data).

Paired sample *t* tests were used to test for differences in uncertainty between bimodal and unimodal conditions, and for differences in predicted and measured visual weights between central and peripheral space. Linear regression analyses were used to assess whether there were significant relationships between measured and predicted reliabilities, and measured and predicted visual weights. A repeated measures ANOVA with location (central, peripheral) as the within-subjects factor and participant group (normally sighted, central vision loss, peripheral vision loss) as the between subjects factor was used to compare cue uncertainty across participant groups.

### Results

Five participants with peripheral vision loss did not complete the peripheral condition, as they were unable to perceive the visual targets presented in peripheral space. Therefore, the results of all 10 participants with peripheral vision loss in the central localization task, but the results of just five participants in the peripheral localization task, are reported here. Figure 2 plots data points and fitted psychometric functions from a representative normally sighted participant and a representative participant with central vision loss in the central localization task.

#### Uncertainty

We first analyzed standard deviations (σ) of fitted functions, a measure of uncertainty—higher values of σ indicate greater uncertainty (lower reliability) of perceptual estimates. Figure 3 plots mean uncertainty for the single cue (Audition, Vision) and Bimodal conditions, and Predicted (ideal observer, MLE) uncertainty, for each group, in central and peripheral conditions. Table 3 reports the results of paired *t* test comparisons of Bimodal uncertainty with (i) each single cue; (ii) the best single cue; and (iii) ideal observer (MLE) predictions.

Comparison with (i) each single cue tests whether, on average, a group showed reduced uncertainty given both cues together (Bimodal) versus either cue alone. The comparison with (ii) the best single cue selects, for each participant, the single cue (Vision or Audition) with the lower uncertainty and compares this with Bimodal performance. This most directly tests whether participants reduced their uncertainty in Bimodal conditions relative to the best single cue, but is also a conservative test. Always selecting the unimodal cue with the lowest uncertainty can lead to a systematic bias to select cues with lower estimated uncertainty than their true uncertainty (due to measurement noise). The comparison with (iii) ideal observer (MLE) predictions tests whether Bimodal uncertainty deviates significantly from MLE predictions. In suboptimal cue combination, Bimodal uncertainty would be expected to be higher than predicted by the MLE.

![Figure 3](image-url)  
*Figure 3.* Measured and predicted uncertainty for visual-auditory localization. Visual, auditory, bimodal, and predicted localization uncertainty, in central (upper panel) and peripheral (lower panel) space, for participants with normal sight, central vision loss, or peripheral vision loss. Error bars show the standard error of the mean (note that this is different from the standard error of the difference, compared in paired *t* tests). Bimodal uncertainty was compared with each single cue’s uncertainty, and also with the ideal (MLE) prediction. (* indicates *p* < .05; ** indicates *p* < .01). See the online article for the color version of this figure.

Figure 4A–B and Table 4 report the results of regression analyses testing whether MLE Predictions predict the Bimodal uncertainties of individual participants. Findings of significant relationships were followed up with tests of whether regression slopes differed significantly from optimal (unity).

Central Localization

All three participant groups in the central localization task (Figure 3, top) showed lower mean uncertainty for bimodal relative to unisensory judgments, although bimodal uncertainty was not (i) significantly lower than that for either single cue, or (ii) significantly lower than the best single cue (see Table 3). For all three groups, bimodal central localization uncertainty was (iii) not significantly different from MLE predictions (see Table 3).

Regression analyses of individual participants’ bimodal uncertainties as compared with their individual MLE predictions (Figure 4A & Table 4) show that the MLE model significantly predicted individual participants’ bimodal reliabilities in all three groups.

Figure 4. Top panel—Predicted and measured audio-visual (AV) reliabilities in central (A) and peripheral (B) space. Lower panel—Predicted and measured vision weights in central (C) and peripheral (D) space. Group means depicted by larger symbols. See the online article for the color version of this figure.
was the group of participants with central vision loss, who had
basis; comparison with unity in Table 4). The notable exception
(Figure 4A–B), and tended not to deviate significantly from opti-
bimodal uncertainty tended to be well predicted by the MLE
estimates relative to unimodal cues (see Figure 3), although the
from the unity (optimal) line in Figure 4.
Table 3), as also seen in the shift of this regression line upward
significantly higher than predicted (see Figure 3, bottom row,
uncertainty showed a significant difference for one group—partic-
Table 3). Comparisons of (iii) bimodal and predicted (MLE)
uncertainty for bimodal relative to unisensory judgments. For
Peripheral Localization
as with central localization, in peripheral space (Figure 3,
measured reliabilities did not significantly deviate from optimal
(unity) for any group (see Table 4).

Peripheral Reliabilities
As with central localization, in peripheral space (Figure 3,
weight predictions at central (Figure 4C) and peripheral (Figure
Peripheral Reliabilities $F_{[2,10]} = 13.0, p < .01^{**}$
$R^2 = .57, \hat{\beta}_1 = .76$
Optimal $t_{[10]} = 1.143, p = .28$
Weights $F_{[2,10]} = 17.3, p < .01^{**}$
$R^2 = .63, \hat{\beta}_1 = 1.18$
Optimal $t_{[10]} = .643, p = .53$

Note. Where the relationship between predictions and measurements was significant, T-tests were used to
assess whether this relationship deviated significantly from optimal (unity).

Furthermore, the slope of the regression line for predicted versus
measured reliabilities did not significantly deviate from optimal
(unity) for any group (see Table 4).

Cue Weighting
Next, we analyzed cue weighting. Figure 4C–D plots individual
measured vision weights against individual optimal (MLE) visual
weight predictions at central (Figure 4C) and peripheral (Figure
Peripheral Localization
For normally sighted adults and participants with peripheral
vision loss, there was a significant linear relationship between
measured and predicted vision weights in central space ($p \leq .01$; see
Table 4, Figure 4C). One-way $t$-tests indicated that the slope of the
regression line for these linear relationships did not signifi-
cantly deviate from optimal (see Table 4). In contrast, for partic-
ipsants with central vision loss, there was no significant relationship
between measured and predicted vision weights ($p = .62$; see
Table 4, Figure 4C).

Peripheral Localization
As in central space, for normally sighted adults, there was a significant linear relationship between measured and predicted
vision weights in peripheral space ($p \leq .01$; see Table 4, Figure
4D), which again did not deviate significantly from optimal (see
Table 4). Participants with peripheral vision loss showed a similar
relationship between measured and predicted vision weights ($p = .075$), but this was not statistically significant, very likely because
of the small sample size ($n = 5$). However, as in central space, for
participants with central vision loss there was no significant rela-
tionship between measured and predicted visual weights ($p = .68$; see
Table 5, Figure 3D).

Overall, the results indicate that for normally sighted partici-
pants and participants with peripheral vision loss (excluding pe-

In both central and peripheral space, both controls and patients with peripheral vision loss showed bimodal uncertainty that did not significantly differ from optimal MLE predictions (Figures 3 & 4). Although bimodal uncertainty was not significantly reduced relative to the best single cue, individual participants’ bimodal uncertainties were well predicted by their individual MLEs (Figure 4A–B), as were individual cue weights (Figure 4C–D). Participants with central vision loss showed a different pattern of results: these participants showed significantly higher bimodal uncertainty than predicted in peripheral space (see Figure 3), and their measured vision weights did not match predictions based on individual cue reliability (Figure 4C–D). This group’s nonoptimal weighting (Figure 4C–D) may explain their higher-than-predicted bimodal cue reliability (Figure 4C–D). This group’s nonoptimal weighting (Figure 4C–D) may explain their higher-than-predicted bimodal uncertainty (see Figure 3). Interestingly, this group also showed unexpectedly high auditory uncertainty in the periphery, indicating that they needed to account not only for their vision loss but also for a loss in auditory localization ability. Finally, localization of the stimuli used did not require (or show) significant reweighting by individuals across central versus peripheral space.

Discussion
This study aimed to understand whether adults diagnosed with progressive visual loss are able to account for the long-term changes to the reliability of their vision. Results showed that normally sighted adults combined visual and auditory location cues optimally in both central and peripheral space, by weighting cues according to their relative reliability. Similarly, patients with visual loss that primarily affected their peripheral vision also weighted visual and auditory cue to location according to their reliability, in line with optimal MLE predictions. In contrast, patients with central vision loss did not weight vision optimally in either central or peripheral space; measured vision weights showed no relation to predictions. These results suggest that human adults

</table>
are able to combine multisensory cues in a way that compensates for some types of long-term progressive sensory changes, but not others.

Previous studies have shown that normally sighted adults can rapidly reweight sensory cues as their relative reliability is manipulated from trial to trial (e.g., Alais & Burr, 2004; Ernst & Banks, 2002). Here we found that adults experiencing progressive peripheral vision loss weighted vision in line with MLE predictions (at least in central space, because results for peripheral space are limited by sample number), as did normally sighted adults. This suggests that, in addition to short-term manipulations of cue reliability, the nervous system can also account for some longer-term changes to sensory reliability following sensory loss.

However, participants with central vision loss only showed a markedly different pattern of results, in that they did not weight visual and auditory information about location according to reliability. This group did not show a systematic tendency to either overweight or underweight the visual cue. Instead, participants’ measured visual weights showed no relationship with optimal reliability-based predictions. Despite this, bimodal localization estimates did not show significantly higher uncertainty compared to the most reliable unisensory cue. Such a result could be explained by complete reliance on the best unisensory cue. However, measured weights did not show a complete reliance on either vision or audition. Hence, the findings suggest that participants with central vision loss combined visual and auditory information, but using suboptimal weights, that is, weights that did not properly account for each individual’s relative cue reliabilities.

Overall, the results show two patient groups with progressive sensory loss, one succeeding and one failing at combining cues according to the MLE rule. Why might the group with central loss, in particular, have failed to weight cues by reliability? An interesting result is that this group also showed strikingly elevated auditory localization uncertainty in the periphery (see similar finding in congenitally blind adults with residual vision by Lessard et al., 1998). It was anticipated that differences across groups would reflect changes to one sense (vision), and that the task for patients, in terms of cue combination, would be to account for progressive changes in this one sense. Instead, the results suggest that the central group had to contend with changes to two senses—potentially a more challenging task for maintaining optimal cue weights than a change only to one sense. This increased difficulty of dealing with changes in both senses could have contributed to this group’s difficulties with maintaining correct cue weighting.

We had not expected differences in auditory localization between these different participant groups. Consequently, one possibility is that the impaired auditory localization of participants with central vision loss is linked in some way to the deterioration of their vision. Future research is needed to address whether this is the case. However, irrespective of why participants with central vision loss showed greater auditory localization uncertainty, the question remains as to why they did not account for the relative reliability of their vision and audition when combining these cues.

It is frequently reported that participants with central vision loss learn to rely on eccentric viewing, developing a preferred retinal locus that avoids the area of central vision loss (Crossland, Engel, & Legge, 2011). Accordingly, the central vision loss patients may have been learning a different correspondence between the auditory, head-centered, spatial map and the visual, eye-centered, representation of space, (as has been demonstrated in animals following a misalignment of visual-auditory cues, e.g., Feldman & Knudsen, 1997; Wallace & Stein, 2007). Patients in the process of learning this new mapping may have perceived a discrepancy in the spatial location of the target via vision versus audition, at least at some of the comparison positions. They may have fixated the required visual targets centrally, which would change the audio-visual mapping from a usual mapping they may have been learning to use during eccentric fixation. Alternatively, they may have fixated the targets eccentrically, but have still been in the process of learning a new audio-visual mapping for eccentric fixation. All participants were asked to keep their head as still as possible (using the chin and forehead rest provided) and to maintain their eye gaze in the direction of the fixation cue throughout the whole experiment. However, eye movements were not systematically monitored. Therefore, another possibility is that this patient group found it particularly difficult to maintain fixation. It would be useful to monitor fixation to differentiate between these possibilities in the future. Nevertheless, either way, on some trials, some patients may not have combined cues in line with reliability-based MLE predictions because of a perceived spatial disparity following changes to their fixation.

Ideal observer models have been developed for tasks in which cues are systematically biased and/or spatially inconsistent (e.g., Burge, Ernst, & Banks, 2008; Körding et al., 2007), but the present study did not measure subjective biases or discrepancies across visual versus auditory cues. We propose that subjective misalignment of cues due to changes in fixation behavior could contribute to apparent failures of cue combination in the central vision loss group, but further research is needed to test this interpretation directly. The perceptual uncertainty we measured may be a combination of uncertainty and of effects due to cues sometimes being perceived as systematically biased or not coming from the same source. This would add noise to measures of uncertainty and of cue weighting, and to measures of optimally predicted cue weighting, which depends on measured uncertainty.

In the main experiment, all participant groups showed visual and auditory discrimination thresholds that deteriorated from central to peripheral space. However, the relative reliability of both cues did not change significantly; participants did not have to adjust their relative reliance on visual versus auditory cues between central and peripheral locations and, accordingly, participants showed similar cue weighting across locations. Consequently, it is not clear whether patients with progressive visual loss account for differences in the relative reliability of visual and auditory cues across their visual field. Follow-up tests using different stimuli that are better suited to finding such differences are needed to establish this.

In summary, the results indicate that when combining visual and auditory cues to location, human adults are able to account for long-term progressive changes to their visual reliability—just as normally sighted adults account for experimental manipulations to visual reliability. However, certain long-term changes to visual reliability that affect the mapping between visual and nonvisual cues may be more difficult to account for. We found that participants with central vision loss did not weight visual information in line with MLE predictions based on cue reliability. Importantly, for this group, the progressive visual change appeared to influence both the reliability of vision and audition. We propose that changes
in the spatial correspondence between audition and vision, due to the
development of perceptual mismatch strategies, may have led to
subjective perceptual mismatches between vision and audition.
Whether such mismatches are present—and whether they are dealt
with in line with ideal observer principles (e., Burge et al., 2008;
Körding et al., 2007)—are questions for future research. It is
possible that developing eccentric fixation to deal with central
vision loss may come at the (possibly temporary) cost to combin-
ing visual and auditory cues for localization. If so, this has inter-
esting implications for the treatment and rehabilitation of adults
experiencing visual loss. Low vision rehabilitation services that
teach patients to shift their visual field from straight ahead to a
peripheral retinal area may want to consider that the accuracy and
reliability of nonvisual senses could be affected. It may be that
patients will gradually learn to correct any misalignments or biases
in visual and nonvisual spatial information that result from relying
on peripheral vision to fixate centrally. However, training pro-
grams in eccentric viewing that include a multisensory component
may be beneficial in facilitating such learning.

Can humans account for progressive visual loss in line with
MLE principles during multisensory cue combination? To our
knowledge, we describe here the first data to address this question.
We found one patient group that followed MLE principles, and one
that did not. We suggest that the latter group may have experienced
changes to cross-modal mapping not captured by the basic MLE
model. If so, then it is possible in theory that the latter group’s
behavior would also be near-optimal, if issues due to remapping
could be taken into account—although the measures we collected
do not allow us to test that here. This interpretation suggests that
in most cases of sensorial loss, humans should be able to account for
changes in the relative reliability of vision in line with MLE
principles; however, further studies with other groups and modal-
ities are clearly needed, including groups experiencing more gra-
dual changes via normal aging (e., Bates & Wolbers, 2014). The
results highlight the need to consider possible changes in cross-
modal mapping, as well as in unimodal reliability, following
sensorial loss.
